Abstract

Regional or national growth distributions can provide vital information on the health status of populations. In most resource poor countries however, the required anthropometric data from purpose-designed growth surveys are not readily available. We propose a practical method for estimating regional (multi-country) age-conditional weight distributions based on existing survey data from different countries. We developed a two-step method by which one is able to model data with widely different age ranges and sample sizes. The method produces references both at the country level and at the regional (multi-country) level. The first step models country-specific centile curves by BCT and BCPE distributions implemented in GAMLSS through a common model. Individual countries may vary in location and spread. The second step defines the regional reference from a finite mixture of the country distributions, weighted by population size. To demonstrate the method we fitted the weight-for-age distribution in twelve countries in South East Asia and the Western Pacific, based on 273,270 observations. We modelled both the raw body weight and the corresponding Z score, and obtained a good fit between the final models and the original data for both solutions. We briefly discuss an application of the generated regional references to obtain appropriate, region-specific, age-based dosing regimens of drugs used in the tropics. The method is an affordable and efficient strategy to estimate regional growth distributions where the standard costly alternatives are not an option.

1. Introduction

A wide range of methods is available for estimating the age-related distribution of human growth [1, 2].

Growth standards are based on such distributions. Growth standards describe how children should grow, and are widely accepted tools for monitoring height, weight and body mass index (BMI). Many countries use standards developed for another country, such as the recently updated international WHO standards for children below 5 years of age [2] and standards for school-aged children and adolescents [3]. In contrast to growth standards, *growth references* describe the actual distribution of growth parameters at population level at a certain point or period in time, i.e. they show how children actually grow in a given population. Growth references provide vital information on the overall health status of a population and can be updated to show changes in health/growth over time [4].

In practice, growth references are rarely available in resource-poor regions since the required purpose-designed national or multi-country growth surveys are costly and logistically challenging. Some nutritional data may however be available from sub-groups within the population from a variety of different sources. Large national household surveys such as UNICEF's Multiple Indicator Cluster Survey (MICS) program and the Measure Demographic Health Survey (DHS) program collect various nationally representative population-level representative demographic and health data. These studies currently typically cover anthropometric measurements in specific population subgroups only, such as children < 3 or <5 years of age, or women of reproductive age (15-45 years). In addition, nutritional data that are representative at the sub-national/district level may be collected as part of demographic surveillance systems (DSS) or other large-scale research efforts.

5
6
7 Despite the availability of these data, there are currently no standardized methods that aim to capture
8 multi-source data to derive reference curves. The use of existing data could be an affordable, efficient
9 strategy when alternatives are not an option, but the success of this approach is highly dependent on the
10 quality of the data used. Obvious problems include the incompleteness of data across age ranges, sex,
11 ethnicity, geographic regions, time periods and/or socio-economic strata. In addition, differences in
12 sampling design and sampling fraction, quality assurance of anthropometric measurements related to
13 the accuracy of measurements, rounding, or calibration of equipment would undermine this approach.
14
15 With this incomplete list of potential drawbacks, one may be tempted to discard the use of existing data
16 altogether. These problems, however, are not unlike those faced when conducting systematic reviews of
17 the effects of healthcare interventions. In the same way the Cochrane guidelines provide
18 recommendations regarding literature searches, data inclusion, data extraction, quality assessment and
19 the appropriate statistical methods of meta-analyses [5]. When handled with care, the use of existing
20 anthropometric data to estimate the distribution of human growth is likely to be informative and of
21 public health relevance, despite their obvious limitations.

38 The methodology for creating growth references for individual populations for whom complete, quality
39 data is available is well established [1, 6, 7]. The modeling of growth data from different sources and
40 regions requires an expansion of current modeling methodology to address three main problems.
41
42

43 Firstly, populations may have different growth distributions with varying median, spread and skewness
44 linked to genetic or nutritional factors. Secondly, existing data typically cover different age ranges and
45 may not be equally available for both genders, whereas conventional methodology is limited to the
46 available age range. The analysis may thus require data extrapolation. Thirdly, country-specific

5
6
7 references may need to be combined into a regional distribution covering multiple countries. This
8
9 requires the overall distribution to be weighted for population size or other factors of interest.

10
11 In this paper we propose a practical method for estimating age-conditional distributions based on
12
13 existing data from multiple sources. We will demonstrate the method by estimating the age-conditional
14
15 distribution of body weight using existing data from countries in South East Asia and the Western
16
17 Pacific. Section 2 introduces the data sources that were used to develop the method. Section 3 describes
18
19 two different modeling options to estimate the age-conditional body weight distribution. Section 4
20
21 presents a method to combine individual country-specific distributions into a weighted regional
22
23 distribution. Section 5 discusses some potential applications of the generated regional reference, in
24
25 particular to calculate optimal age-based drug dosing regimens. Section 6 discusses the strengths and
26
27 limitations of the method and concludes the paper. The appendix contains the R code for fitting the
28
29 main models.

37 2. Source data

38
39
40 Through literature searches and communication with individual researchers, research institutions, and
41
42 national and international agencies, we compiled community-based data from twelve Asian countries
43
44 covering the WHO Western Pacific and South-East Asian regions. Body weight was measured for
45
46 273,270 individuals (62,523 males, 210,747 females) aged between 2 weeks to 50 years. Only
47
48 population-based datasets collected as random samples of the population and direct weight
49
50 measurements were included. Data based on self-reported body weight were excluded. Table 1 provides

7 a breakdown of the number of observations per country. Detailed methods of the quality assessment,
8 selection criteria and collation procedures of these different datasets will be described elsewhere.
9

10
11 All body weight measurements (in kg) were expressed as weight-for-age deviation scores, or Z scores,
12 relative to the CDC 2000 growth reference [8]. The Z score for persons aged 20 years and older was
13 calculated using the reference for the 20-years olds. Any weight gain in adults thus implies a higher Z
14 score. Outliers for weight were examined by first plotting the Z score by age for each study separately,
15 followed by searching for discontinuities in the distributions. As the spread between countries was
16 fairly large, we decided to apply liberal cut-off values of $Z < -10$ SDS and $Z > +6$ SDS for the automatic
17 exclusion of outliers. Asymmetric cut-offs were chosen to reflect the fact that the mean weights of our
18 data were considerably lower than the reference set (based on the US population). The percentage of
19 outliers thus removed was equal to 0.12% of the data, and was no greater than 0.63% for any one
20 country.

32

33
34
35 The remaining observations were randomly split into two data sets: a *training* set of 70% of the records
36 for fitting and checking the model, and a *test* data set of 30% of the records to assess the predictive
37 validity and the risk of over-fitting the obtained model.
38
39
40

41
42 Figures 1 and 2 contain simple scattergrams of body weight against age for the twelve countries. Note
43 that each subplot exhibits the familiar pattern of increasing body weight with age, but there are
44 substantive differences between countries with respect to the ages covered, and the density of the
45 available data. Also, some countries are covered by two or more studies. For example, one could
46 recognize three different studies among Vietnamese males. In total 77% of the data represented
47 females. This unusual sex ratio is explained by the sampling strategy of the large-scale, national DHS

6 and MICS surveys, which contributed 83% of the compiled data. In these surveys, anthropometric data
7
8 is collected from children of both sexes up to the age of 3 to 5 years, from women of reproductive age,
9
10 but not from adult males. This focus on adult females in these surveys is linked to the known
11
12 association between maternal anthropometrics and child and reproductive health indicators.

3. Models for country-level age-conditional weight distributions

21 This section focuses on modeling the age-conditional body weight distribution for individual countries
22 through a common model. The modeling framework is based on the Generalized Additive Model for
23 Location, Scale and Shape (GAMLSS) [9]. GAMLSS provides a flexible model for a univariate
24 response variable Y based on explanatory variables. The distribution of Y in GAMLSS can be selected
25 from a large collection of distributions, including highly skewed and kurtotic distributions. The package
26 for fitting GAMLSS is available in R [10]. The analysis presented here used the GAMLSS 1.8.7 library
27 running under R 2.6.2.
28
29
30
31
32
33
34
35
36

37 Here we consider a special case of the GAMLSS model where we model the outcome Y using both a
38 continuous explanatory variable x , a function of age and a categorical variable c for country (indexed by
39 subscript j):
40
41
42
43
44
45
46
47
48

$$Y \sim D(\mu, \sigma, \nu, \tau)$$

50
51
52
53
54
55
56
57
58
59
60

$$g_1(\mu) = \alpha_{1j} + h_1(x)$$

$$g_2(\sigma) = \alpha_{2j} + h_2(x) \tag{1}$$

$$g_3(\nu) = \alpha_{3j} + h_3(x)$$

$$g_4(\tau) = \alpha_{4j} + h_4(x)$$

where D represents the distribution, either the Box-Cox t (BCT) distribution or the Box-Cox Power Exponential (BCPE) distribution. Equation (1) expresses the location (μ), scale (σ), skewness (ν) and kurtosis (τ) parameters of the distribution as smooth functions of explanatory variables x . The term α_{kj} is the constant intercept for country j for distribution parameter k ($k=1,\dots,4$), $h_k(x)$ is either a polynomial or a smooth function of x , and $g_k(\cdot)$ is a known monotonic link function chosen by the user. Males and females are modeled separately.

We use the following stepwise procedure for selecting a country-level model:

1. Select Y (raw weight or weight-for-age Z score)
2. Select functions $g_k(\cdot)$ and distribution D (BCPE or BCT)
3. Select transformation x of variable age
4. Assess the need to split the countries into two or more homogeneous subgroups, if age-dependent weight distribution of sub-groups is considerably different, using the Schwarz Bayesian information criterion (SBC)

5. For each homogeneous subgroup of countries, select size of penalty for each effective degree of freedom used in the models for μ , σ , ν and τ on the training data, for application with the generalized Akaike information criterion (GAIC), or a combination of worm plots and associated mean squared error (MSE) plots
 6. Optimize models for each individual subgroup of countries
 7. Confirm overall model fit using the test data

Selecting Y, i.e. modeling W or Z. The function $Z = f(W, t)$ converts measurements in kg (W) into standard deviation scores (Z) relative to a chosen reference, while $W = f^{-1}(Z, t)$ is its inverse. We present models for both W and Z . The first approach uses the raw weight in kg and simultaneously describes the variation in weight between different ages and between countries. The second approach models Z , and concentrates on modeling the variation between countries.

Distributions. Previous applications of GAMLSS include centile estimation using the BCPE and BCT distributions to a variety of anthropometric measures against age [11] and [12]. Both distributions are four parameter distributions, allowing modeling of location, scale, skewness and kurtosis. Both distributions allow modeling of positive and negative skewness. The difference between the BCPE and BCT distributions is that BCPE allows modeling of both platykurtosis and leptokurtosis, while BCT only models leptokurtosis. The BCT distribution has been found to provide a better fit to a response variable with high leptokurtosis, e.g. [12], while BCPE has the flexibility to fit a response variable with platykurtosis or moderate leptokurtosis.

Transformation of the age scale. To simplify the model needed to fit the median weight over the course of life, we applied a transformation to age t . In general, it is beneficial to expand the ages where growth velocity is high, and compress age where growth velocity is low [6]. Based on the optimized SBC, a simple square root transformation of age was found to appreciably enhance the model fit. We also tried the age transformation method proposed by Cole, whereby the median curve is first fitted against age in the usual way, then it is refitted but using the initial median curve rather than age. The refined median curve is then plotted against the original age.[12] However, this did not provide an improved fit to the data as judged by the SBC. All modeling was therefore done in the scale of \sqrt{t} .

Model selection. The optimal (effective) degrees of freedom in each of the smooth h functions above were selected based on the combination of two diagnostic tools:

- a. Minimization of the generalized Akaike information criterion (GAIC), given by $GAIC = -2l + \#df$, where l is the log likelihood function, $\#$ is a penalty for each degree of freedom used in the model and df is the total (effective) degrees of freedom used in the model. The penalty $\#$ chosen should be sufficiently large to avoid over-fitting (which results in centile curves that are insufficiently smooth) and sufficiently small to avoid under-fitting (which results in a poor fit to the data). We use the SBC, a specific GAIC where the penalty $\# = \log n$. As the penalty is related to the size of the dataset, this reduces the risk of overfitting.
- b. In addition, worm plots per country and the associated mean squared error (MSE) were used to guide these choices [7]. The worm plot is a de-trended QQ-plot created for a number of (usually 16) age intervals. The shapes of the worms indicate where and how we can improve the fit of the model. Worm plots were drawn on the level of the individual countries, and a

1
2
3
4
5
6
7 customized software routine was created for this purpose. Our strategy involved the
8
9 comparison of two worm plots side by side, where we gradually increased the degrees of
10
11 freedom $df(\mu)$, $df(\sigma)$, $df(\nu)$, and $df(\tau)$. The degrees of freedom df were chosen at the point at
12
13 which only very minor differences can be seen between solutions df and $df+1$. In order to
14
15 quantify this effect, we calculated the quantitative measures, β_0 to β_3 , which describe the shape
16
17 of each worm. The amount of fit of the μ -component in the model is measured by shape
18
19 coefficient β_0 . For age groups $g=1, \dots, 16$ we calculate the mean squared error $MSE(\beta_0) =$
20
21 $\sum_g \beta_{0,g}^2 / 16$ over the 16 panels of the worm plot. This is done separately for country and shape
22
23 coefficients β_0 to β_3 on a grid of models for $df(\mu)$, $df(\sigma)$, $df(\nu)$, and $df(\tau)$.
24
25
26
27

28 The resulting local (country-level) references were plotted in the form of age-dependent curves for μ , σ ,
29
30 ν , and τ by using the `predict.gamlss` function.
31
32

33 In the following sections we present two alternative options to model either body weight W against age
34
35 (referred to as the ‘raw score model’), or models the weight for age Z score against age (referred to as
36
37 the ‘Z score model’).
38
39
40

41 3.1. Raw score model

44 Here we model directly the body weights W against age and country using a GAMLSS model of type
45
46 (1), applying the following steps:
47
48

- 49 1. Set distribution to BCT, and change the default link function from identity μ to $\log(\mu)$
50
51
- 52 2. Set age transformation: $x = \sqrt{t}$
53
54
55
56
57
58
59
60

3. Set age smoothing method: Cubic splines
4. Assess the homogeneity between countries: Split the countries into two groups: Thailand versus the remaining countries (see below)
5. Optimize models for the 2 individual homogeneous subgroups using the GAIC (i.e. SBC), MSE and worm plots.

The rationale for this model choice is as follows. The BCT distribution was found to give a better overall fit to W than the BCPE distribution. The log link for μ was found to give a better fit than the identity link. The log link for μ provides a multiplicative model for μ , i.e. the countries have multiplicative effect on μ , while the identity link for μ would provide an additive model for μ . Cubic splines provided flexible smooth curves in age.

Figure 3 displays the $MSE(\beta_0)$ per country for males at increasing degrees of freedom $df(\mu)$ before the split of the model into subgroups. For most countries the fit increases (i.e. the MSE decreases) as the model becomes more flexible. A notable exception is Thailand. We interpret this as an indication that the age-dependent weight distribution for males from Thailand is different from that in the other Asian countries. This is supported by the fact that the sum of the two deviances for the separate models is substantially lower than the deviance from the model fitted to all countries at once. We therefore decided to model Thailand separately. For the females, we came to a similar conclusion.

Hence four models for W were fitted: male Thailand, male other countries, female Thailand and female other countries. All four models for W were in the form given by:

$$W \sim \text{BCT}(\mu, \sigma, \nu, \tau)$$

$$\log(\mu) = \alpha_{1j} + h_1(x)$$

$$\log(\sigma) = \alpha_{2j} + h_2(x) \tag{2}$$

$$\nu = h_3(x)$$

$$\log(\tau) = h_4(x)$$

The male ‘other countries’ model includes different constant intercepts α_{1j} and α_{2j} for each of the other countries (indicated by subscript j) for each of μ and σ respectively. Similarly for the female ‘other countries’ model. The male and female Thailand models are in the same form, but without the country effect, i.e. setting $\alpha_{1j} = 0$ and $\alpha_{2j} = 0$.

The functions $h_k(x)$ for $k = 1, 2, 3$ are smooth functions of x for all four models, while function $h_4(x)$ is linear in x , i.e. $h_4(x) = \alpha_4 + \beta_4 x$ for all models except the female ‘other countries’ model where it is a smooth function of x .

Table 2 provides the chosen degrees of freedom for smoothing (on top of constant and linear terms in x) for the h functions of μ , σ , ν and τ . Note that all four models have different fitted smooth functions and the fitted linear models for $h_4(x)$ in three of the models (where the smoothing degrees of freedom is zero) are also different.

The use of the log link for μ affects the interpretation of the median curve. For the other countries model (2) we have:

$$\mu = e^{\alpha_{1j}} e^{h_1(x)} = \mu_j H_1(x)$$

$$\sigma = e^{\alpha_{2j}} e^{h_2(x)} = \sigma_j H_2(x)$$

where $H_1(x) = e^{h_1(x)}$ and $H_2(x) = e^{h_2(x)}$ are smooth functions of x , while $\mu_j = e^{\alpha_{1j}}$ and $\sigma_j = e^{\alpha_{2j}}$ are scaling factors for μ and σ for the country j ($j = 1, \dots, J$). Hence the fitted functions for μ (the median weight) against age (for the different other countries) differ only in their scaling factor μ_j .

Figure 4 plots the estimates of μ_j against σ_j . The medians for Bhutan and Philippines were about 1.1 to 1.3 times the common median curve. The data for India had a high variance, whereas the spread in the data was low in Vietnam.

3.2. Z score model

This section discusses modeling Z instead of W . The Z measure expresses all data relative to the 1997 Dutch weight-for-age references. Fitting the model involved the following steps:

1. Set distribution to BCPE, using default link functions
2. Set age transformation: $x = \sqrt{t}$
3. Set age smoothing method: orthogonal polynomials for model exploration, switch to cubic splines for final models

4. Add a constant = 11 to the Z score data before fitting (see below for rationale).
5. Split the countries into two groups: Thailand versus the rest
6. Optimize models using the GAIC (i.e. SBC), MSE and worm plots.

The distribution of Z is platykurtic, i.e. it has thicker tails than the normal distribution. The BCPE distribution is able to model this feature of the data [11]. As the BCPE is only defined for positive values, we add a constant $\delta=11$ to the data before fitting, based on the minimum deviance found over a grid of δ -values using the profile likelihood.

All models for Z are given by:

$$Z \sim \text{BCPE}(\mu, \sigma, \nu, \tau)$$

$$\mu = \alpha_{1j} + h_1(x) \tag{4}$$

$$\log(\sigma) = \alpha_{2j} + h_2(x)$$

$$\nu = h_3(x)$$

$$\log(\tau) = h_4(x)$$

with $h_1(x)$ and $h_2(x)$ are smooth functions of x whose degree of freedom is to be specified, and where $h_3(x) = \alpha_3 + \beta_3x$ and $h_4(x) = \alpha_4 + \beta_4x$ are linear in x . As results were largely insensitive to the type of smoother, we chose the fastest method (in terms of computer processing time), orthogonal polynomials,

1
2
3
4
5
6
7 for model exploration, and cubic splines for the final models. The model allows for different constant
8 intercepts α_{1j} and α_{2j} for the countries in the models for each of μ and σ respectively. The model
9 allows that countries can differ in their mean level and their variation on the Z score scale, but not in
10 other aspects.
11
12
13
14

15
16 The model requires a specification of the degrees of freedom, $df(\mu)$, $df(\sigma)$, $df(\nu)$, and $df(\tau)$. It is
17 essential to assess the fit of the models at the country level since the composition of the sample can
18 differ from that of the regional population. We studied the behavior of the worm plots at the country
19 level, with its vertical range set equal to -0.5 to +0.5. Smoothing coefficients were fixed at the point at
20 which no major improvements in fit occurred anymore for successively $df(\mu)$, $df(\sigma)$, $df(\nu)$ and $df(\tau)$.
21 Table 3 lists the settings of the Z score models. After fitting, all results were back-transformed into the
22 original body weight scale.

9 references.

10
11 We also compared the worm plots and the centiles of the raw score and Z score models. As an example,
12
13 Figure 7 contains the worm plots for Bangladesh males under both models. The use and interpretation
14
15 of worm plots as diagnostic tools for modeling growth reference curves has been described in detail
16
17 elsewhere.[8] While some differences are certainly present, both model solutions are largely, if not very
18
19 comparable.
20
21

22
23 Table 4 contains the percentage of persons that fall below the 3rd, 10th, 50th, 90th and 97th centiles of the
24
25 country for both models. We calculated the percentages from the test data, which were not used to
26
27 estimate the model. Table 4 indicates that most percentages are located within 1 or 2 percent points of
28
29 the expected value. Larger differences may occur when sample size is low (e.g. Philippines). It was not
30
31 possible to estimate the percentages for Bhutan. There is not much difference between the raw score
32
33 and Z score models. Table 4 provides evidence that the fitted country level references adequately model
34
35 the empirical distributions in each country.

4. Combining countries into a regional weight-for-age distribution

42
43
44
45 On completion of the country-level modeling, the regional distribution is determined by mixing the
46
47 smoothed country-level distributions. To do this, let $f_j(y) [=f_j(y|X=x)]$ be the distribution of Y given $X=x$
48
49 for country j , for $j=1,2,\dots,J$. The regional distribution $f_Y(y) [=f_Y(y|X=x)]$ is a finite mixture distribution
50
51 with known mixture weights w_j proportional to the population size P_j , given by

$$f_Y(y) = \sum_{j=1}^J w_j f_j(y) \text{ where } w_j = \frac{P_j}{\sum_{j=1}^J P_j} \text{ for } j=1,2,\dots,J. \tag{5}$$

Similarly the regional cumulative distribution function $F_Y(y)[=F_Y(y|X=x)=\text{prob}(Y \leq y | X=x)]$ is given by

$$F_Y(y) = \sum_{j=1}^J w_j F_j(y), \tag{6}$$

where $F_j(y)$ is the cumulative distribution function of Y given $X = x$ for country j . The regional centile y given x , for a specific centile percentage $100p\%$, is defined by $F_Y(y) = p$, or equivalently $y = F_Y^{-1}(p)$, requiring the inverse cumulative distribution function $F_Y^{-1}(p)$. A centile curve for y against x , for a specific centile percentage $100p\%$, is obtained by finding the centile y for a sequence of values of x . In the raw score model, we mix the country-level distribution of W . In the Z score model, the mixture is created using the weight-for-age Z score, and subsequently back-transformed into the kg scale.

The generated regional centile curves are given in Figure 8 for ages from birth to 50 years. All in all, the regional reference from the raw score and Z score model agree quite close, except for the 18 year olds males. The primary reason for this is that the available male data are very sparse at this age (cf. Figure 1). Thus, the local shape of the model is not steered by empirical evidence. Our use of two distinct models highlights where in the model the solution seems to depend on assumptions. Provided that the models are flexible enough, we expect such discrepancies to disappear for more dense data, e.g., as was indeed the case in the females.

5. Application

The generated growth references may have a range of practical applications. Examples include monitoring the nutritional status in a country or a region, estimating age-specific prevalence of underweight or overweight, and setting regulations that involve body weight, e.g. maximum number of person allowed in a transport vehicle or elevator.

We developed the method with the specific aim to establish a standardized tool to determine safe and effective age-based dosing regimens for antimalarials and other drugs used in the tropics [13]. Malaria causes an estimated 300 to 500 million episodes of clinical malaria, resulting in up to 1 million deaths each year. The regulatory drug development process for antimalarials typically results in weight-based dosing recommendations. In practice, however, the majority of fevers in malaria endemic areas are treated with over-the-counter antimalarial drugs without involvement of the formal health sector, or in other situations where functioning weighing scales are not available [14]. In these settings age is widely used as a proxy for weight. There are currently no standardized procedures to devise age-based proxies for the weight-based recommendations that typically result from the regulatory drug development process. This has contributed to considerable variability in existing age-based dose regimens for antimalarials, at times resulting in poor, but widely-used regimens, particularly in those who bear the brunt of the malaria burden, namely young, rapidly growing children [15]. An optimal age based regimen corresponds to the lowest risk of over- and under dosing in a given population. In order to derive optimal regimens, we need the actual reference distribution of weight by-age in that population, rather than the available international growth standards. The proposed method provides a tool to estimate these age-conditional distributions of body weight based on the available data.

6. Discussion

We developed a two-step method for fitting centile growth curves for a set of countries. Our method is able to model data with widely different age ranges and sample sizes, and produces references both at the country level and at the regional level. Within the model, individual countries can vary in location and spread. We demonstrated the method by fitting the weight-for-age distribution in twelve countries in South East Asia and the Western Pacific, and were able to achieve a good fit between the final model and the original data.

Our two-step finite mixture approach is an improvement over methods that require pooled data for a single population. The first step generates country-specific references that extrapolate information from similar countries. Given sufficient overlap in the ages, this step allows for extrapolation of the country references into age ranges that were not observed. The second step defines the regional reference as a finite mixture distribution of the country references. We used mixture weights proportional to country-level population size, but other choices are certainly possible (e.g. malaria prevalence).

The two-step approach allows for tremendous flexibility and could be useful for mixing growth references within other settings. For example, suppose that we want to create a smooth transition between two disjoint references on a given age range. We could chose mixture weights to gradually change with age, thus setting $(1,0)$ at the start of the age range setting $(0,1)$ at the end, with a smooth transition in between. Alternatively, we could mix different subsamples (e.g. ethnic background, breast feeding status) in the appropriate proportions, or estimate secular trend in the distribution as one or more model parameters.

1
2
3
4
5
6
7 The country references are well-defined BCPE or BCT distributions, but the regional mixture
8 distribution is not. Whether this is a problem depends on the context. In our application for defining
9 age-based drug regimens, it was straightforward to calculate the percentage of adequately dosed
10 children from the regional centiles. Calculating Z scores relative to the new regional reference would
11 require a BCT or BCPE distribution. We fitted BCPE and BCT models to the centiles that approximate
12 the regional reference to a high degree of accuracy. This fitted distribution could then be used to
13 calculate Z scores.
14
15
16
17
18
19
20
21

22 We used two definitions for Y , the raw score and the Z score. Despite some methodological differences,
23 both approaches resulted in very similar regional and country level estimates, adding credibility to the
24 validity and robustness of the procedure. Both approaches appear to have sufficient flexibility built into
25 the model, which means that the results are predominantly dictated by the underlying data. Of course,
26 this also implies that, as always, care is needed when data are sparse. The choice between modeling raw
27 scores or Z scores is primarily a matter of convenience and familiarity. Modeling the raw score
28 provides a model in terms of original units, which is convenient. Furthermore, it is the only option if
29 appropriate external references are lacking. The Z score model scales data to an external growth
30 reference, so that the location of a country can be expressed relative to this reference. The Z score
31 model does not need to model the typical age-related shapes (e.g. the growth spurts during infancy and
32 puberty, adiposity rebound) that appear in the original scale, thus allowing the use of a simpler model.

59
60

On the other hand, the Z score approach may have difficulty in modeling populations with widely
different timings. A prerequisite is that the reference used to obtain the Z scores is in phase with the
new data, so that for example the timing of the pubertal growth spurt is similar in the two. If pubertal
growth occurs earlier in the target population than in the reference population, this would manifest

itself as a rise in Z scores around the start of puberty in the target population, followed by a decrease, and leading up to an asymptote that could differ from the pre-pubertal mean. If the timing differs between different countries, then smoothing the Z scores tends to flatten out phase differences. This might have been the case for the males in Figure 6, where the curves around age 15 are different in shape under the two models. We cannot be sure however since there are only few data points around that age. In principle, we can allow for phase variation by using more flexible smoothing methods that incorporate time shifts, but that requires larger samples around puberty than are currently available. It is not known whether the raw score model is more efficient in handling this problem than the Z score model. A third option is to follow both routes, as presented here. This is more work, but it provides insight into the robustness of the final model under alternative modeling choices.

The age range for the analysis is 0-50 years. Some countries (Cambodia, Thailand, Bangladesh, India and Nepal) have substantial numbers of adult subjects. One concern is that those subjects may dominate the analysis, and swamp the child data. We reran our final models on the data that exclude any persons >25yr, and compared the results to our original curves. Overall, the results were very similar, with only some small differences near the ages close to 25 years, presumably due to edge effects. We prefer the analysis 0-50 years since that analysis uses all available data.

The Z score method requires a growth reference. We have chosen to use the CDC 2000 reference, which is a country-specific reference based on the 1977 NCHS data. We initially planned to use the new WHO 2007 re-analysis of the NCHS data.[3] The WHO 2007 weight-for-age references only includes children up to the age of 10 years, however, and fails to cover the age interval 10-19 years. We therefore opted to use the CDC reference instead. The choice of reference, however, does not appear to be critical. Repeating the analysis using the Dutch 1997 reference instead of the CDC reference,[16]

1
2
3
4
5
6
7 resulted in different solutions when viewed in the Z scale (as expected), but similar when those results
8
9 were transformed into the W scale. It thus appears that the Z score method is robust against the choice
10
11 of the reference.

12
13
14 As part of the model building process we explored the need to fit more complex models. Varying
15
16 slopes for age were initially included in the raw score model for μ in the female data for Bangladesh,
17
18 Cambodia and Nepal. Though this significantly improved model fit, the effect was only noticeable for
19
20 the upper age range. The absolute difference of the fitted median was 0.28 kg when averaged over all
21
22 ages, and 0.1 kg when averaged for ages 0-20 years. The largest deviation, 1.6 kg, occurred for
23
24 Bangladesh females aged 50 years. As the differences of this magnitude are unlikely to have practical
25
26 consequences, we refrained from modeling varying slopes in the final model. Likewise, other model
27
28 parameters that we explored, like study period and country effects for the models of ν and τ , had only
29
30 minor effects and were therefore omitted.
31
32

33
34
35 Our method uses readily available data, which is an affordable and efficient strategy. We are, however,
36
37 cognizant of the limitations of the generated growth reference curves. As with any model, the quality of
38
39 the modeled output depends on the quality and representativeness of the underlying data. Though we
40
41 included only studies where sampling was based on random sampling, the country-level curves we
42
43 derived may not be representative if data are missing over a large age range for that country and if the
44
45 growth rate in the missing age group differs from that in other countries contributing to the model.
46
47 Furthermore, due to the sparsity of data from certain countries, we did not restrict ourselves to recent
48
49 studies only. While most studies were conducted in the last 10 years, there were a few older surveys.
50
51 The generated reference curves thus need to be updated as more recent, complete data becomes
52
53 available.

3
4
5
6
7 Asia is home to a vast and diverse portion of the world's population, with differences in weight
8 distribution within and between Asian countries linked to ethnicity, social and economic conditions,
9 differences in diet, degrees of urbanisation, and nutritional transitions in recent times. Our regional
10 reference curves quantify known, but nevertheless striking differences of the actual Asian growth
11 relative to the CDC 2000 growth references. Over 50% of the population in Asia is estimated to have
12 weights that are below the 3rd percentile of the CDC references.

17
18
19

20
21 There are initiatives to conduct national household surveys like UNICEF's MICs surveys and Measure
22 DHS surveys on a more regular basis (every 3-4 years). Regular high-quality national household
23 surveys would offer the opportunity to expand their current collection of representative anthropometric
24 data in young children and women of reproductive age, to a wider age range. If such data were to
25 become available in the near future, they could readily be taken up into our approach. Doing so would
26 help strengthen and solidify the information base of regional growth estimates, and potentially provide
27 a tool to monitor country-level and regional changes in nutritional status. Until then, our method based
28 on existing anthropometric data is an affordable and efficient strategy to monitor nutrition and health at
29 several levels.

Appendix: R code for fitting models

Example of data structure of Asian males:

ID	country	age	weight	WAZ	WAZ11
3	Viet Nam	4.79	50	-2.514	8.486
9	Viet Nam	5.29	52	-2.186	8.814
10	Viet Nam	5.56	69	-0.144	10.856

where the column age indicates the square root of age in years, where WAZ is the Z score and where $WAZ11 = WAZ + 11$. The raw score model and the Z score model for the 'other countries' (excluding Thailand) were fitted in R by:

```
library(gamlss)

fit.w <- gamlss(formula = weight ~ cs(age, df = 13) + country,
               sigma.formula = ~cs(age, df = 7) + country,
               nu.formula = ~cs(age, df = 3, c.spar = c(-1.5, 2.5)),
               tau.formula = ~cs(age, df = 0),
               family = BCT(mu.link = "log"),
               data = asianMRest, c.crit = 0.1)

fit.z <- gamlss(formula = WAZ11 ~ cs(age, df = 8) + country,
               sigma.formula = ~cs(age, df = 2) + country,
               nu.formula = ~1,
               tau.formula = ~cs(age, df = 1),
               family = BCPE,
               data = asianMRest, c.crit = 0.1)
```

Table 1: Number of cases and age range per country and sex of South-East Asian countries.

Country	Females			Males

Figure captions

- Figure 1 Weight (kg) by age (years) of males in 12 Asian countries. Sample sizes and age ranges for which data is available vary widely between countries.
- Figure 2 Weight (kg) by age (years) of females in 12 Asian countries. Sample sizes and age ranges for which data is available vary widely between countries.
- Figure 3 Mean squared error (MSE) per country for increasingly flexible models for the median curve. $MSE(\beta_0)$ quantifies model fit as the squared shape coefficient β_0 is averaged over 16 worm plot panels. The quantity $df(\mu)$ is the degrees of freedom in the cubic spline of $\sqrt{\text{age}}$ in the median curve. A decreasing trend corresponds to a better fit. Note that the fit of Thailand deteriorates for more flexible models.
- Figure 4 Scattergrams of the two country parameters (location and spread) for the raw score model, by sex. The horizontal axis is a multiplicative location factor of the common μ -component. A larger value indicates a higher median weight of the data. The vertical axis is a multiplicative scale factor of the common σ -component. A larger value implies a higher level of variability in weight in the data.
- Figure 5 Scattergrams of the two country parameters (location and spread) for the Z score model, for males and females. The horizontal axis is the shift in location (in SDS) relative to the CDC 2000 reference. A larger value indicates a higher median weight of the data. The vertical axis is a multiplicative scale factor of the common σ -component. A larger value implies a higher level of variability in weight in the data.
- Figure 6 Median (P50) weight-by-age curves per country by model types (raw score and Z score) and sex. For comparison purposes, the median and -2SD lines of the CDC 2000 reference have been added. Note that the Asian people are on average substantially

1
2
3 lighter than the CDC 2000 reference.
4
5

6 Figure 7 Example of worm plot used to assess the accuracy of the model fit for males in
7 Bangladesh based on the test data. 'Flatter worms' indicate a better fit. The fit of the Z
8 score model (top) and the raw score model (bottom) is similar. Similar age-stratified
9 diagnostic plots were used by country and sex. Age groups are ordered from the
10 lower-left corner panel to the upper-right corner panel.

18 Figure 8 Regional centiles (P3, P10, P50, P90, P97) obtained after weighting the fitted country-
19 specific distributions according to population size. Centiles from the raw score (W)
20 model (red) and Z score model (green) are plotted in the same figure. Males (left) and
21 females (right).
