Abstract

Persistent insecticides sprayed onto house walls, and incorporated into insecticide-treated bednets, provide long-acting, cost-effective control of vector-borne diseases such as malaria and leishmaniasis. The high concentrations that occur immediately post-deployment may kill both resistant and susceptible insects. However, insecticide concentration, and therefore killing ability, declines in the months after deployment. As concentrations decline, resistant insects start to survive while susceptible insects are still killed. The period of time after deployment, within which mortality of resistant individuals is lower than that of susceptible ones, has been termed the ‘window of selection’ in other contexts. It is recognised as driving resistance in bacteria and malaria parasites, both of which are predominantly haploid. We argue that paying more attention to these mortality differences can help understand the evolution of insecticide resistance. Because insects are diploid, resistance encoded by single genes generates heterozygotes. This gives the potential for a narrower ‘window of dominance’, within the window of selection, where heterozygote mortality is lower than that of susceptible homozygotes. We explore the general properties of windows of selection and dominance in driving resistance. We quantify their likely effect using data from new laboratory experiments and published data from the laboratory and field. These windows can persist months or years after insecticide deployments. Differential mortalities of resistant, susceptible and heterozygous genotypes, after public-health deployments, constitute a major challenge to controlling resistance. Greater attention to mortality differences by genotype would inform strategies to reduce the evolution of resistance to existing and new insecticides.

Keywords: insecticide resistance, window of selection, window of dominance, malaria, insecticide resistance management, vector-borne diseases, drug resistance, dose-response
1. Introduction.

Seventeen percent of human infectious diseases are estimated to be transmitted by vectors such as mosquitoes, ticks and fleas (WHO, 2014a). Malaria alone, despite recent declines, killed an estimated 435,000 people in 2017 (World Health Organisation, 2018). Insecticides, used in public health interventions to control vector-borne diseases, have saved millions of malaria deaths (Bhatt et al., 2015) and averted deaths and morbidity from other infections such as dengue, zika, lymphatic filariasis, Leishmaniasis and Japanese encephalitis. The control of such diseases is threatened by insecticide resistance, that is now widespread in many vector species (Gould, Brown, & Kuzma, 2018; Ranson & Lissenden, 2016). Insecticide-resistance management (IRM) programs have been designed and implemented to slow the evolution of resistance (Denholm & Rowland, 1992; Gould et al., 2018; Huijben & Paaijmans, 2017; Roush, 1989; Sternberg & Thomas, 2017). The design of effective, appropriate IRM strategies depends on understanding the forces that drive the spread of insecticide resistance. Most IRM strategies have been developed for agricultural use, adapted for public health and imported into public health programmes (IRAC, 2011; WHO, 2012). One important operational factor in insecticide deployment is that insecticide concentrations decline after application. In agriculture, this decline tends to be rapid, either as a deliberate policy to avoid residual insecticides on human food, or because the insecticide is rapidly washed off crops by rain or degraded by sunlight. Conversely, most public health applications are specifically designed to deploy highly persistent insecticides in order to maximize their long-term impact and cost-effectiveness (White, Conteh, Cibulskis, & Ghani, 2011). The key objective of this paper is to explore how long-term persistence of insecticides, used in many public health applications, is likely to accelerate the evolution of insecticide resistance.

We investigate the impact of insecticide persistence by borrowing the term 'window of selection' which has previously been applied to the evolution of drug resistance in malaria (e.g. Kay & Hastings, 2015; Slater, Okell, & Ghani, 2016) and antibiotic resistance in bacteria (Gullberg et al., 2011). We illustrate the basic principles in Figure 1A. The highest insecticide concentrations occur immediately after application/deployment and, in the best case scenario, are sufficient to kill both
resistant and susceptible insects. In that case the window of selection is closed. As concentrations decline, the mortality of resistant insects declines before that of susceptible ones, leading to the differential survival that drives the evolution of resistance; the selective window is open. In many places, resistance to target doses means that the window of selection is already open on deployment. After further decline, insecticide concentrations reach levels such that both resistant and susceptible forms survive, resistance is not selected for and the window closes again. If there are fitness costs, the mortality of resistant individuals may be higher than that of susceptible individuals at lowest concentrations and this would be expected to select for a return to susceptibility. The window of selection for resistance could be defined in terms of differential fitness, as anything that allows the resistant individuals to leave more progeny will promote selection (such as better mating success (Rowland, 1991)). However, for operational purposes it is likely that mortality is the most important and measurable factor.

Previous discussion of windows of selection has compared resistant and susceptible 'strains'. In malaria and bacteria this easily equates to selection on a single gene (or plasmid) because these organisms are haploid when they encounter the drug in humans, so in the simplest cases have only two genotypes i.e. R and S. However, insects are diploid with potential for three distinct genotypes at a resistance locus (i.e. RR, SR and SS), making the dynamics of selection more complicated (Figure 1B). As insecticide concentrations decline, the relative mortality of the SR genotype changes, reflecting increasing dominance of the resistance gene (see also Denholm & Rowland, 1992; Gould et al., 2018; Levick et al., 2017 Figure 1). At initial high concentrations, dominance is expected to be low and the mortality of the SR close to the SS. As concentrations decline dominance is also expected to decline and mortality of the SR becomes closer to the RR. We use the term 'window of dominance' to describe the region within the window of selection where dominance is greater than zero. The importance of dominance for the evolution of insecticide resistance has been recognised previously (Bourguet, Genissel, Raymond, & Raymond, 2000; Gould et al., 2018; Levick et al., 2017; Mallet, 1989), but the effect on selection of changing dominance, in response to insecticide concentration, has not been quantified.

2.1 Population genetic and computational analyses of windows of selection and dominance

Mortality estimates of all three genotypes (SS, SR and RR), where available, allowed us to quantify the magnitude of selection for resistance using two approaches. Firstly, using population genetics to calculate the selective advantage of resistance over a single generation. Secondly, using a published computer simulation (Levick et al., 2017; South & Hastings, 2018) to calculate how rapidly evolution drives resistance allele frequency to 50%.

Both approaches require the proportion of the population exposed to the insecticide and the frequency of the resistance allele. The frequency of the resistance allele alters the proportion of insects in each of the three genotypes, and hence the impact of dominance. We used two illustrative starting resistance allele frequencies 0.01 and $10^{-4}$ (i.e. 1% and 0.01%). The proportion of the population exposed to the insecticide was set at 30% for both sexes [increasing it gave higher selective advantage and lower times-to-resistance but qualitatively similar results (Fig S2.1)].

2.1.1 Population genetics to calculate the selective advantage of resistance

Let the fitnesses of the SS, SR and RR genotypes exposed to the insecticide be $W_{ss}$, $W_{sr}$ and $W_{rr}$ respectively. Here we assume fitness is the proportion of the genotype that survives exposure. Let $p$ and $q$ (=1-$p$) be the frequency of resistant and susceptible alleles respectively. Assuming there is no selection on those not exposed to the insecticide (i.e. that there are no fitness costs of resistance) and that the genotypes are initially in Hardy-Weinberg equilibrium (i.e. the frequencies of RR, SR and SS genotypes are $p^2$, 2$pq$, $q^2$ respectively), then the frequencies of $p$ and $q$ next generation, denoted $p'$ and $q'$ are:

$$p' = \frac{x[p^2w_{RR} + 2pq \times 0.5 \times w_{SR}] + (1-x)[p^2 + 2pq \times 0.5]}{W}$$

$$q' = \frac{x[2pq \times 0.5 \times w_{SR} + q^2w_{SS}] + (1-x)[2pq \times 0.5 + q^2]}{W}$$

This article is protected by copyright. All rights reserved
where $\overline{W}$ is a normalising factor equal to the sum of the numerators. The relative fitness of the R allele is given by $p'/p$ but fitness is often broken down to $w=1+z$, where $z$ is the selective advantage (we avoid the conventional symbol, $s$, for selective advantage to avoid confusion with the S allele). The value of $z$ can therefore be obtained as

$$z = \frac{p'}{p} - 1$$

We generally present values of $z$ (rather than $w$) because changes in its value are more obvious in the plots. Note that $z$ will also depend on the frequency of the resistance allele because this frequency determines the relative frequency of insects in the three genotypes.

2.1.2 Computer simulation to calculate times to resistance thresholds

Computer simulation of the evolution of resistance used a published model (Levick et al., 2017; South & Hastings, 2018). The model represents the genetics of a single randomly mixing population and, as in standard population genetic models, tracks frequencies of alleles and genotypes without tracking demography. Hence, it does not include changes in population size or dispersal. The mortalities of resistant and susceptible genotypes, at different time points, were used to calculate model inputs, namely insecticide effectiveness (mortality of the SS), resistance restoration (the proportion of SS mortality that is prevented by the RR genotype) and dominance. The proportion of the population exposed to the insecticide was set at $x=0.3$ and initial starting frequencies at 0.01 and $10^{-4}$, as above. A 'time-to-resistance' was calculated as the number of generations taken to reach a resistance allele frequency of 50%. This illustrates the changing selective pressure at each concentration and is compatible with previous analyses using this metric to quantify the rate of evolution of resistance (Birget & Koella, 2015; Levick et al., 2017; South & Hastings, 2018).

2.2. Laboratory experiments quantifying the duration of windows of selection

We conducted two experiments to quantify windows of selection in terms of insecticide concentration ranges and timescales post application. Windows of selection were indicated where there was a difference in mortality between resistant and susceptible mosquito strains. Note that,
because these experiments used strains rather than known genotypes, they did not allow us to measure windows of dominance. The first experiment exposed resistant and susceptible strains of *Anopheles gambiae* to filter papers impregnated with deltamethrin at a range of concentrations and measured mortality. The second experiment exposed resistant and susceptible strains of *Anopheles gambiae, Anopheles funestus* and *Aedes aegypti* to different surfaces (cement, wood and mud) sprayed with deltamethrin. These surfaces were stored at temperatures and humidity representative of sub-Saharan Africa. Mortality was measured at regular intervals in the 18 months after spraying. Full methods of both experiments are provided in the SI, part 1.

2.3 Literature search for existing data to estimate windows of selection and dominance

We searched the literature for other work reporting differences in mortality between resistant and susceptible strains, or individual RR, SR, SS genotypes, that can be used to quantify windows of selection and dominance. Details of search methods are provided in SI part 3.

All figures were created in R using ggplot2 and patchwork (Pedersen, 2018; R Core Team, 2017; Wickham, 2009).

3. Results.

3.1 theoretical approaches for estimating evolution of insecticide resistance within windows of selection and dominance

The selective advantage of the resistance allele can be calculated from the mortalities of the three genotypes in our idealised plot Figure 1B, and is shown in Figure 1C. Selection for resistance starts to occur as declining concentrations allow the window of selection to open. There is then a rapid increase in selective advantage as the window of dominance opens, due to declining
mortality of the SR. Selective advantage remains high throughout the window of dominance, only declining to zero once concentrations become sufficiently low that all SS survive the same as RR. These patterns are similar for different resistance frequencies except that lower frequencies give lower selective advantage and a greater increase on entering the window of dominance.

The selective advantage, shown in Figure 1C, operates over a single generation. The same pattern (although inverted) occurs when selection is compounded over generations in the computer simulation to estimate time-to-resistance. Figure 1D plots the time until resistance allele frequency reaches 50%, a conventional endpoint in many studies of insecticide resistance (e.g. Birget & Koella, 2015). The shortest time values (i.e. most rapid selection) occur in the window of dominance. For the lower resistance starting frequency, the simulation does not reach the resistance threshold within 500 generations when outside of the window of dominance. Time to resistance may be >500 generations as the window starts to open, but falls to 21 generations when selection is greatest.

The magnitudes of the selective advantage and time-to-resistance are both dependent on the proportion of the population exposed to the insecticide. In Figure 1 an exposure value of 0.3 is used. Settings with higher exposure values had higher selective advantage and lower times to resistance, but a qualitatively similar pattern of greatest selection within the window of dominance (SI Fig S2.1). In summary, both the population genetics equation and simulations indicate evolution of resistance within the window of selection, and faster evolution within the window of dominance.

3.2. laboratory experiments illustrating windows of selection

Resistant and susceptible Anopheles gambiae strains were exposed to different deltamethrin concentrations (Figure 2). The observed mortality pattern was very similar to the idealised window of selection shown in Figure 1A. At high concentrations, mortality is high for both strains; a window of selection is open at intermediate concentrations where mortality is higher for the susceptible than the resistant strain; at low concentrations, mortality is low for both strains. The window of selection operates over a 320 fold range of concentrations; opening around the highest concentration of 0.8% and closing around 0.0025%.
In operational settings, the time (rather than concentration range) for which windows of selection are open, is the more important driver of resistance. Figure 3 shows the changing mortality over 18 months, for resistant and susceptible strains of three mosquito species, exposed to three deltamethrin sprayed substrates. Large differences, between the mortality of susceptible and resistant strains, can be seen in all combinations of species/substrate, clearly confirming the presence of windows of selection. In all cases, the windows of selection seem to be open immediately after spraying, and not to have closed by month 18. The clearest example is for An. gambiae (Figure 3, upper panels), where the window of selection is open at near maximum extent over the full 18 month period after spraying. The results are equally clear-cut for An. funestus (Figure 3 middle panels), where the window of selection is open for the whole 18 month period, although maximal differential mortality does not arise until around 3 months post treatment. In Ae. aegypti (Figure 3, lower panels), the window of selection is open for 18 months, but the difference in mortality between resistant and susceptible strains is slightly less than in the two Anopheline species. The apparent increase in mortality of the resistant strain on wood, between 5 and 18 months after spraying, is counter-intuitive and probably reflects declining colony health. Nevertheless resistant mortality remains lower than susceptible, suggesting the window of selection remains open.

3.3. Published work illustrating windows of selection

Our laboratory experiments above indicated windows of selection. In Table 1 we summarise other published studies illustrating windows of selection and dominance. These are further described in the SI, part 3 together with replotted data. These published studies confirm the results described above, i.e. that windows of selection are routinely observed and that their magnitude is large, often covering several hundred-fold changes in concentration, and typically persisting for many months or years. As an illustrative example, Figure 4 shows changing mortality of Anopheles strains in the months after spraying deltamethrin and clothianidin (Sumishield), replotted from Agossa et al. (2018). For deltamethrin, free flying mosquitoes in hut trials (Fig 4A) suggested a window of selection of at least 8 months and those in cone bioassays (Fig 4C) suggested 5 months. For clothianidin, a newer insecticide, there appears to be a window of selection opening 6 months after spraying (Fig 4 B & D).
Windows of dominance can be estimated from rarer published studies reporting mortalities of RR, SR and SS genotypes exposed to a range of insecticide concentrations or times after deployment (Table 1). Windows of dominance, where SR mortality is less than SS, are observed in all studies, but exhibit qualitatively different patterns. In one example, with cattle ticks, the window of dominance occurs over a narrow range because the mortalities of SR and SS decline together and are close to each other (Figure 5A). In another example, with Culex mosquitoes, the window of dominance is relatively wide as a result of a greater concentration gap between the SR and SS mortality curves (Figure 6A). The theoretical predictions from these study data are similar to those from the idealised example shown in Figure 1 B & C, i.e. selective advantage and time to resistance (e.g. panels B & C of Figs 5&6) are most intense during the window of dominance. This is particularly true for lower starting frequencies of resistance. The changes in the measures of selection vary according to the mortality patterns described above. For the ticks (Fig 5), there is a single peak in selection at a relatively low concentration, due to the SR mortality not declining until low concentrations. A longer period of high selective advantage is shown for Culex (Fig 6), because the window of dominance is open over a wider concentration range.

These results show the importance of dominance, and that the precise nature of mortality differences between genotypes, with concentration, is needed to know the implications for selection. Often those data are not available. To illustrate how different selection can be under different dominance values, we ran our simulation model under three scenarios; a best-case with dominance constant at zero, a worst-case with dominance constant at 1 and an intermediate-case the same as our idealised example in Fig 1B. The results showed that uncertainty in dominance values, at either high or low concentrations, could lead to differences in predictions of times-to-resistance of hundreds of generations (Fig 7).
4. Discussion.

Windows of selection and dominance are straightforward ideas that emerge from three simple principles. Firstly, that the mortality of resistant strains is lower than susceptible ones, when exposed to some insecticide concentrations. Secondly, that insecticide efficacy declines with decreasing concentration, or its surrogate, time since deployment. Thirdly, that dominance of resistance genes is not a fixed genetic parameter, but is likely to increase as concentrations decline. These principles combine to create a window of selection, in units of time or concentration, where insecticide resistance is selected, and within which a window of dominance occurs where selection is much stronger. We provide idealised representations of these windows of selection and dominance in Figure 1. We show, using data generated by ourselves (Figures 2 and 3) and others (Figures 4 to 6 and SI section 3), that this idealised representation matches observed field and laboratory data.

The window of selection in our specific example of deltamethrin and *An. gambiae*, extended over about a 320-fold concentration range (Figure 2). Operationally, it is the length of time these windows are open, and the patterns of differential mortality within the window, that are the critical factors driving insecticide resistance. Our sprayed surface experiment shows that these differences, between resistant and susceptible mortality, can last for more than 18 months (Figure 3). Published data, for spray and nets, suggest windows of selection can act over wide concentration ranges and be open for months or years (Table 1).

The most accessible examples of windows of selection are obtained by comparing resistant and susceptible strains, over a range of concentrations or times post-deployment. The reasoning is that the resistant and susceptible strains can represent the range of genotypes potentially present in a local population. The problem with this comparison is that it is usually unknown whether the strains differ at only a single locus (i.e. a comparison between RR vs SS), at a small number of loci, or whether a significant polygenic component is present. Comparisons made between insects of known genotype are logistically more complex, as they usually require generating a F1 cross, but are much more informative as dominance coefficients can be inferred and both window of selection and window of dominance can be quantified. Our analyses applied to published data indicate highest selection occurs within these windows of dominance (Figs 5,6, S3.5, S3.6).
We have formulated a methodological framework to interpret windows of selection and dominance in diploids. It is important to note that previous authors have identified different parts of this story, for example, that mortality and dominance change over time with insecticide concentration (e.g. Denholm & Rowland, 1992; Gould et al., 2018; Roush, 1989), and that the mortality of different strains or genotypes responds differently over time (e.g. McKenzie & Whitten, 1982; Wanjala et al., 2015) or concentration (e.g. Georgiou & Taylor, 1986; Li, Davey, Miller, Guerrero, & George, 2008). The potential for more persistent insecticides to speed the rate of evolution of resistance was demonstrated more than 30 years ago by computer simulations (Taylor & Georgiou, 1982) and experiments with houseflies (Taylor, Quaglia, & Georgiou, 1983). Our work is the first we know of to attempt quantify changing selection over time or declining insecticide concentration.

4.1 Caveats
We have provided a more detailed understanding of the implications of declining insecticide concentrations, but we have still had to make simplifications and there are, inevitably, caveats to our interpretations. We include little consideration in our analysis of the implications of bioassay reliability, polygenic resistance, competitive release or costs of resistance. We discuss them briefly as follows.

Firstly, mosquitoes do not naturally encounter insecticides in cone and bottle bioassays, so there is some doubt whether findings based on bioassays reflect mortality that occurs in the field (Malima et al., 2008). The use of bioassay data is supported by the fact that the windows of selection shown in Figure 4 A are based upon free flying mosquitoes in experimental huts (Agossa et al., 2018) and show a very similar pattern to the cone bioassays in Figure 4B. In addition, Churcher et al. (2016) and Sherrard-Smith et al. (2018) show evidence that bioassay results are good predictors of mortality in hut trials of insecticidal nets and sprays respectively.

Secondly, our predictions of selection strength assume resistance is coded by a single gene. We recognise that resistance is frequently a polygenic trait encoded by alleles at many genes, each with a small effect (see discussion in Ffrench-Constant, Daborn, & Le Goff, 2004; Groeters & Tabashnik, 2000). Theory predicts that polygenic resistance will also generate windows of
selection, containing regions of higher selection similar to the window of dominance. We outline this argument further in SI part 5.

Thirdly, we have only considered the selective advantage of resistance in terms of the reduced mortality of resistant phenotypes. There is also the potential for ‘competitive release’, where resistant phenotypes have an additional advantage, due to the suppression of susceptibles by a drug or insecticide. Competitive release has been recognised as important for the evolution of drug resistance by parasites within hosts (e.g. Hastings, 2011; Read, Day, & Huijben, 2011), and may also be relevant for insecticide resistance, if competition between individuals is high. Such competition is likely in small breeding pools where larvicides may be applied (Russell et al., 2011), and may potentially drive competition between egg-laying females for access to quality, sparsely-populated breeding sites. Competitive release, where it does occur, could contribute to the length and magnitude of windows of selection by increasing the selective advantage to resistance. We note, however, that the evolution of drug resistance is a different system, where absolute fitness and the ability of a genotype to create enough cells to cause disease and transmission can be more important (Day, Huijben, & Read, 2015) than the relative fitness that is likely to promote the evolution of insecticide resistance.

Fourthly, we have paid little attention to potential fitness costs of resistance, except for noting that our conceptual model of the window of selection can accommodate costs, as a decrease in mortality of resists below susceptibles to the right of Figure 1 A. Fitness costs could similarly be incorporated into plots including heterozygotes, but we chose to exclude them here for simplicity and because the evidence for them is not conclusive (ffrench-Constant & Bass, 2017). High costs of resistance could create a region at low concentrations, after the window of selection, where resistance is selected against.

Finally, we emphasise that this work focuses only on the evolution of insecticide resistance, which is, of course, not the only measure of the success or failure of an insecticide intervention. If the evolution of resistance was the only concern then the best strategy would be to use no insecticides at all. Our modelling does not take into account mosquito population change or disease transmission, which would both be expected to increase as insecticide concentrations decline. For a combined modelling approach, including the effect of insecticide interventions on mosquito
populations, the evolution of resistance and resulting disease outcomes see Barbosa, Kay, Chitnis, & Hastings (2018). Note that this earlier work, as with all previous models that we are aware of, did not consider the likely impact of declining insecticide concentrations and the presence of the windows of selection and dominance.

4.2 Policy implications and conclusions.

We speculate that three aspects of insecticide interventions are most likely to affect the duration, and magnitude, of windows of selection and dominance.

1) Target doses and quality of application, influence whether windows are open on deployment.
2) The rate of decline in concentration, influences when the windows open and close.
3) The interval before the intervention is replaced, influences when windows are closed.

We have demonstrated that selection is highest within the window of dominance. This high selection can be avoided on initial deployment by ensuring that concentrations are high enough to kill all heterozygotes. This is the approach taken in agriculture to maintain the effectiveness of transgenic insecticidal crops (see SI part 4). Transgenic crops keep producing insecticidal toxins, so declining concentration is not the issue for them that it is for public health. Thus, in public health declining concentration can open the window of dominance, which can remain open until the intervention is replaced.

If interventions are not replaced or reapplied, our work shows that selection for resistance may persist long after deployment, due to continued slight advantages of resistance. Selection can be as intense at low concentrations, when susceptible mortality is low and resistant mortality is zero, as it is at higher concentrations, when susceptible mortality is high and resistant mortality is moderate (Figures 1,5,6). For example, the Culex data in Figure 6 show an insecticide concentration of 0.0007 ppm gives a higher selective advantage than the concentration 0.06. The corresponding mortalities of RR,SR,SS are 0,88%,100% in the first case, and 0,0,24% in the second. Thus, a situation where only 24% of the susceptible mosquitoes are being killed could be selecting for resistance more than one where 88% of the SR and 100% of the SS are being killed. This potential of low concentrations to promote resistance has also been demonstrated for antibiotics (Gullberg et al., 2011). Also, note that low insecticide concentrations are likely to lead
to more mosquitoes and thus a greater potential for disease transmission and dispersal of resistant mosquitoes.

Bednets too have high potential to promote selection long after deployment, due to their endurance. Nets collected after 7 years use in Tanzania still caused 40-50% mortality of susceptible strains in a hut trial (Malima et al., 2008) and after 4 years use in Cameroon gave susceptible mortalities of 3-83% in cone bioassays (Boussougou-Sambe et al., 2017). Whilst the mortality of resistant strains was not measured, it would be expected to be less than that of susceptible strains, suggesting windows of selection continue to be open after 4-7 years. The current WHO advice (WHO, 2014b) is to keep using bed nets, even if they have already been in use for years, unless a new one becomes available. This is based on the personal protection benefit, from both the physical barrier and some residual (but low) mosquito killing. Currently WHO documents on measuring and dealing with ageing nets include no consideration of their potential role in selecting for insecticide resistance (WHO, 2011, 2013b, 2014b). Insecticidal effectiveness against susceptible mosquitoes after 3 years is included in initial net acceptance criteria (WHO, 2013a). Mortality beyond this has been removed from considerations of net life because of difficulties measuring it (WHO, 2013c, 2014b).

Our results highlight the importance of considering declining insecticide concentration in the evolution of insecticide resistance. To our knowledge, existing models of the evolution of insecticide resistance have not allowed inputs such as insecticide effectiveness and dominance to change over time (e.g. Birget & Koella, 2015; Levick et al., 2017; Barbosa, Kay, Chitnis, & Hastings, 2018; South & Hastings, 2018). There are important implications of changing insecticide concentrations for the epidemiology of disease transmission, both directly through altering mortality rates of vectors, and indirectly through driving increasing levels of resistance. Recent work has shown both how declining concentrations and levels of resistance influence transmission (Sherrard-Smith et al., 2018). There remains an important knowledge gap of exactly how declining concentrations are likely to drive the evolution of resistance, threatening the effectiveness of control measures. Different insecticide-based intervention strategies will each have different sizes of beneficial effects (reducing mosquito populations and disease transmission), and different sizes of detrimental effects (promoting the evolution of resistance). There is a lack of data and understanding to inform such trade-offs. Management decisions, such
as choosing between an intervention with one long lasting insecticide or repeatedly applying short lasting ones, are not straightforward. In addition, trade-offs will depend on the timescale of evaluations i.e. short-term impact on disease transmission vs longer-term impact on resistance and future transmission. These are complex decisions that we do not address here; we simply argue that extensive windows of selection and windows of dominance will, almost inevitably, arise in public-health deployments of long-acting insecticides, and that these windows will need to be incorporated into such evaluations. We agree with Huijben & Paaijmans (2017), that a greater understanding of the evolutionary processes causing resistance is needed to develop better strategies to manage it. We have shown how the forces driving the evolution of resistance can be usefully documented, interpreted and quantified in terms of windows of selection and dominance. We argue that focusing attention onto the relative mortalities of resistant, susceptible and heterozygous genotypes, over time, is necessary to inform strategies to reduce the evolution of resistance to existing and new insecticides.

Acknowledgements: Members of the IVCC for many fruitful discussions and suggestions. Hilary Ranson who was recipient (with IH and DM) of funding that allowed the windows of selection to be quantified as concentrations and who shared her knowledge of past literature relating persistence of insecticides and selection for resistance. Patricia Graves for providing the raw data from Anshebo et al. 2014 and Gedeon and Aprielle (Brackery) Wills for doing the assays in Ethiopia. Three anonymous reviewers and the associate editor for improving the paper considerably.

*Duration of windows of selection (WoS) and dominance (WoD) is given as approximate x-fold difference in concentration or in units of time (i.e. concentration on closing divided by concentration on opening). Note that WoD can only be determined if mortality is by genotypes.*
**Figure 1.** Idealised windows of selection and windows of dominance for insecticide resistance. A. Window of selection when there is only data on resistant and susceptible strains: selection for resistance occurs when resistant strains have lower mortality than susceptible ones (yellow shaded region). Fitness costs of resistance may cause the mortality of resistant insects to exceed that of susceptible ones at low concentrations, as shown at the lower right, and resistance will be selected against. B-D. Idealised windows of selection and dominance when resistance is encoded by a single gene and there are data on mortalities for all three genotypes (SS, SR and RR). The x-axis is shared between panels B-D. Panel B illustrates how the mortality probabilities change for each genotype and the row of numbers along the top of the plot is the dominance of resistance at each time point. Panel C shows selective advantage per generation which is highest within the window of dominance. Panel D shows predicted time until resistance allele frequency reaches 50% for simulations started at each point along the X axis in panel B. Times to the 50% resistance threshold are lowest within the window of dominance and the threshold of 500 generations is not reached for points outside of the window of selection. Panels C & D assume that 30% of all mosquitoes are exposed to the insecticide, equivalent plots at different exposure levels are shown in the SI.
Figure 2. Window of selection in units of insecticide concentration for *Anopheles gambiae* exposed to deltamethrin. Points show the percentage mortality 24 hours after exposure, by replicate, for resistant and susceptible strains and lines show a locally weighted smoother (loess). The x axis is plotted from high to low concentrations, for consistency with time plots because concentrations decline with time after deployment. Vertical dashed lines indicate the WHO standard discriminating concentrations at 1x, 5x and 10x used to estimate resistance intensity (WHO, 2013a).
Figure 3. Windows of selection, in units of time, associated with deltamethrin exposure of three vector species; *Anopheles gambiae*, *Anopheles funestus* and *Aedes aegypti*. Deltamethrin initially applied to three different substrates (cement, mud, and wood tiles) then kept in a stability chamber mimicking African field conditions. Percentage mortality was assessed by cone bioassay, 24 hours after exposure, for resistant and susceptible strains. Mortality lines show a locally weighted smoother (loess). Windows of selection are open for all species-surface combinations across the whole time of the experiment. (Control mortality of mosquitoes exposed to tiles not treated with insecticide is shown in SI figure S2.3, indicating no difference in resistant and susceptible mortality in the absence of insecticide).
Figure 4. Windows of selection in units of time for *Anopheles* mosquitoes in sprayed experimental hut trials in Benin; data extracted from Figures 3 to 6 of Agossa et al. (2018). A & B. Free flying mosquitoes, C & D. Cone bioassays. A. & C. show 24 hour mortality for deltamethrin and B. & D. show 120 hour (5 day) mortality for clothianidin (Sumishield) (a slower acting neonicotinoid insecticide for which 5 day mortality is a better measure). A window of selection is open from deployment for deltamethrin and starting to close by month 8. Conversely, for clothianidin the window of selection is initially shut and opens in later months.
Figure 5. Windows of selection and dominance, in units of concentration, associated with permethrin resistance in the tick species *Boophilus microplus*; Panel A shows the mortality data reported in Figure 1 of Li et al. (2008) from bioassays on tick larvae of a susceptible, resistant and F1 crosses exposed for 24 hours. The row of numbers along the top of panel A is our calculation of dominance of resistance at each concentration. Panels B and C show our measures of selection plotted along the same concentration x axis. Where mortality data was absent we extrapolated to 0 or 100% to extract values for the calculation (e.g. mortality of RR was assumed to be 0 at concentrations ≤1% and mortality of RS, SR was assumed to be 100% at concentrations >0.05). We used the mean mortality of the two heterozygous genotypes (in the original experiment, the SR came from SS fathers and RR mothers, RS from the reverse). Panel B shows how selective advantage within a single generation changes during the windows of selection and how it depends on the starting frequency of resistance. Panel C shows simulation results of the number of generations needed to reach a resistance allele frequency of 50%.
Figure 6. Windows of selection and dominance, in units of concentration, associated with permethrin resistance in Culex quinquefasciatus. Panel A shows data reported in Georghiou & Taylor (1986) from larvae exposed to the insecticide. The row of numbers along the top of panel A is our calculation of dominance of resistance for each concentration. Panels B and C show our measures of selection calculated on the same concentration x axis. Where mortality data was absent we extrapolated to 0 or 100% to extract values for the calculation (e.g. mortality of RR was assumed to be 0 at concentrations < 0.1 ppm and mortality of SS was assumed to be 100% at concentrations >0.01 ppm). Panel B shows how selective advantage changes during the windows of selection and how it depends on the starting frequency of resistance. Panel C shows simulation results of the number of generations needed to reach a resistance allele frequency of 50%.
Figure 7. Implications for selection of not knowing dominance values. Panels A to C show three scenarios for a window of selection, Panel A. is a best-case where dominance is constant 0, mortality of the SR is the same as the SS, and there is no window of dominance. Panel B is an intermediate scenario the same as Fig 1B. Panel C is a worst-case scenario where dominance is a constant 1, and the window of dominance is open for the whole of the window of selection. The x-axis is shared between panels A-D. Panel D shows predicted time until resistance allele frequency reaches 50% for simulations started at each point along the X axis in panels A-C. The difference between the best and worst-case scenarios can be hundreds of generations.
