**Abstract.** Vector control methods that mobilize and impact rapidly during dengue, Zika, and chikungunya outbreaks are urgently needed in urban contexts. We investigated whether one person using a handheld aerosolized insecticide could achieve efficacy levels comparable to targeted indoor residual spraying (TIRS), using pyrethroid-resistant *Aedes aegypti* in a semi-field setting with experimental houses in Mexico. The insecticide product (H24, a carbamate and pyrethroid mixture), available over-the-counter locally, was sprayed only on known *Ae. aegypti*-resting surfaces, for example, walls less than 1.5 m and dark hidden areas. In six identical houses with paired bedrooms, one bedroom was treated, and the other remained an untreated control. Each week for 8 weeks, 100 female pyrethroid-resistant *Ae. aegypti* were released in each bedroom and followed up daily. Mortality rates in treated bedrooms exceeded 90% for at least 2 weeks, and more than 80% (89.2; 95% CI: 79.98–98.35) for 3 weeks or more. Mortality rates in control houses were zero. Results demonstrate that the immediate impact of TIRS can be delivered by one person using existing products, at an estimated cost for the average household in Mexico of under US\$3 per month. Triggered by early outbreak signs, dissemination via community hubs and mass/social media of instructions to treat the home immediately, with monthly re-treatment thereafter, provides a simple means to engage and empower householders. Compatible with integrated vector management strategies, it enables self-protection even if existing agencies falter, a situation exemplified by the potential impact on vector control of the restrictions imposed during the 2020 COVID-19 pandemic.

### INTRODUCTION

The mosquito *Aedes aegypti* is the primary vector worldwide of the arboviruses causing dengue, chikungunya, and Zika.<sup>1–3</sup> After decades of vector control programs based on larvicide treatment or elimination of breeding sites, and control of adult mosquitoes by outdoor space spraying (e.g., truck-mounted ultralow-volume spraying), the highly endophilic *Ae. aegypti* adult mosquito population can also now be targeted.<sup>4</sup> Indoor residual spraying (IRS) of resting sites of *Aedes* spp. mosquitoes was recommended by the Vector Control Advisory Group of the WHO<sup>5</sup> in 2016, to improve vector control and a primary intervention for immediate response in the context of Zika transmission.<sup>5</sup>

Typically, IRS aimed at controlling *Ae. aegypti* is termed targeted indoor residual spraying (TIRS) because it is applied by focusing on the vector's known intra-domiciliary resting sites. These are interior lower walls (< 1.5 m), surfaces behind/under furniture, inside wardrobes/closets, etc., and other dark or shaded objects/areas in dormitories.<sup>6–9</sup> Trials in experimental houses in Mexico have shown that TIRS using an appropriate insecticide achieved and maintained more than 80% mortality for 4 months, but with shorter spraying time and 30% insecticide in comparison with “classic” IRS, where all wall surfaces are treated.<sup>6</sup> As a result, the “Manual for IRS in Urban Areas for *Aedes aegypti* Control” was developed by the Pan

American Health Organization to guide institutional implementation of TIRS by vector control programs.<sup>10</sup>

Previously, the use of handheld commercial aerosolized insecticides (CAIs) applied as a residue by householders has been encouraged as part of strategies to transfer control to communities.<sup>11,12</sup> The routine use of household aerosols for mosquito control is common, particularly during outbreaks of dengue, chikungunya, and Zika. In recent studies in the Mexican state of Yucatan, nearly 94% of households reported using insecticide aerosols regularly, 70–90% of which were CAIs, at an estimated annual cost of approximately US\$25 per house.<sup>13–15</sup> Here, we report an evaluation of the residual efficacy of over-the-counter household insecticide aerosols applied as TIRS against pyrethroid-resistant *Ae. aegypti* within experimental houses in Merida, Mexico.

### MATERIALS AND METHODS

The study was carried out in six identical houses at the Ciudad Caucel experimental house site in Merida, Yucatan, Mexico, between July and September 2017, the rainy season in Yucatan when more than 80% of dengue transmission occurs.<sup>16–18</sup> These houses had been used previously for studies on TIRS and *Ae. aegypti*.<sup>6</sup> Each single storey concrete house had two bedrooms, and all 12 bedrooms were fitted with identical furniture and other contents, typifying that seen in local houses (Figure 1A). Detailed specifications of the experimental houses and contents are given in Dunbar.<sup>6</sup> To prevent any mosquitoes from escaping from the bedrooms, all windows and doors were screened on both the outside and inside of each dormitory before the study began. In addition, a screened door was built into the main entrance of each

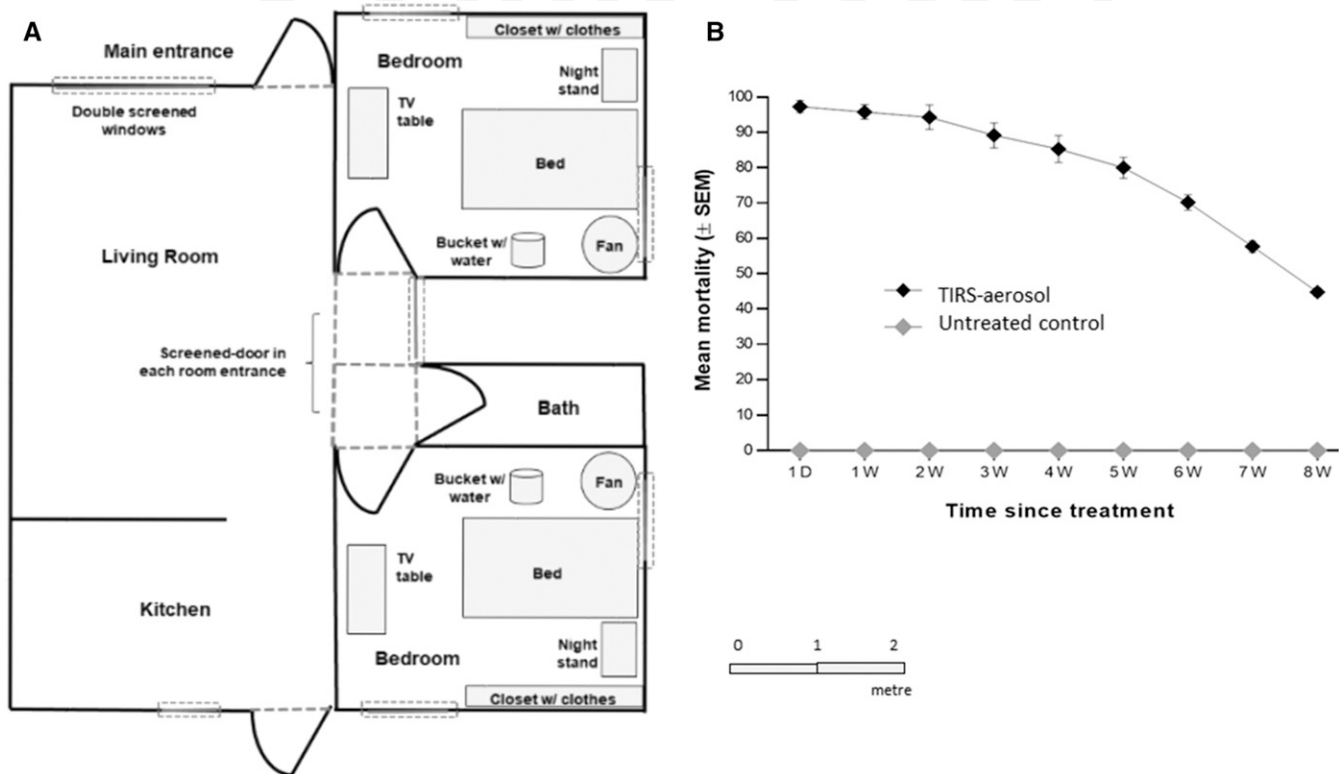

FIGURE 1. (A) Layout of an experimental house, showing the positions and sizes of furniture in the identical bedrooms. All external and internal windows and doors were screened to prevent mosquito passage. A bucket (0.5 L water) and a 40-cm-diam. oscillating fan stabilized relative humidity and temperature in each bedroom. The interiors of all six experimental houses were identical. (B) Mortality of pyrethroid-resistant *Aedes aegypti* by targeted indoor residual spraying (TIRS) with a household aerosolized insecticide over time. Symbols denote sample means, and error bars are the standard error of the mean. D = day; W = weeks.

bedroom to allow personnel to enter and exit while preventing mosquitoes from escaping (Figure 1). Ant baits (Antex Gel, Allister de México) were placed next to door or at any location where ants might have entered.

The insecticide aerosol used was H24<sup>®</sup> Poder Fulminante Ultra Eficaz<sup>®</sup> (propoxur 4.60 g/kg, tetramethrin 1.03 g/kg, and fenvalerate 4.55 g/kg; Industrias H24, Mexico), sprayed in 10-second bursts, 30 cm from the treated surface, as instructed by the label. Insecticide was applied uniformly and evenly with horizontal strips with a flow rate for the formulation of 1.9 g/second (SD = 0.15), to deposit an estimated 0.01 g of insecticide per square meter. Application was made by the same individual at each of the experimental houses.

The treatment was randomly allocated to one bedroom inside each experimental house, and the second bedroom was a control (no treatment). The treated surfaces were lower walls (< 1.5 m), curtains, under the bed, on and behind the nightstand and TV table, and the closet (Figure 1A). The insecticide was allowed to dry for 24 hours before the first mosquitoes were released.

Adult female *Ae. aegypti* from a colony of the San Lorenzo strain at UADY (Unidad Colaborativa para Bioensayos Entomológicos, UADY, Merida, Mexico) were used in all tests. This strain was recently colonized from local populations and is resistant to pyrethroids, but fully susceptible to carbamates.<sup>19,20</sup>

In all bedrooms, 100 sugar-fed female mosquitoes (no blood meal), aged 3–7 days post-eclosion, were released at 24

hours posttreatment, and every week thereafter for 8 weeks, until the average mortality reached 50%. At 24 hours after release, each room was inspected by a team of four field technicians who retrieved any live mosquitoes using a Prokopack aspirator and dead mosquitoes by hand.

For each sampling period, mortality per room was calculated by dividing the number of dead individuals by the number of individuals released. Mean mortality rates between arms were compared using a Student's *t*-test, with significance expressed at the 5% level. A cutoff efficacy criterion of 80% mortality at 24 hours was established as the mean value for

TABLE 1

Mean (±standard error of the mean [SEM]) and 95% CIs of 24 hours post-exposition mortality of a pyrethroid-resistant *Aedes aegypti* strain

Time since treatment	Mean (±SEM)	95% CI	P-value
1 day	97.3 (±1.71)	92.95–101.72	< 0.001*
1 week	95.8 (±2.07)	90.51–101.16	< 0.001*
2 weeks	94.3 (±3.45)	85.46–103.20	0.004*
3 weeks	89.2 (±3.57)	79.98–98.35	0.025*
4 weeks	85.3 (±3.79)	75.59–95.08	0.109
5 weeks	80.0 (±2.92)	72.49–87.51	0.500
6 weeks	70.2 (±2.24)	64.40–75.93	0.996
7 weeks	57.7 (±1.60)	53.54–61.79	1.000
8 weeks	44.8 (±1.17)	41.83–47.83	1.000

\* Average mortality is not statistically higher than 80%, *t*-test for a sample ( $\alpha = 0.05$ ,  $n - 1$  degrees of freedom (df)).

rejecting or accepting the null hypothesis, following the criteria established for biological efficacy tests by the WHO.<sup>21</sup>

**Ethics statement.** This was an experimental study where laboratory-reared unfed mosquitoes were released into uninhabited houses, and hence did not require an institutional review board approval.

## RESULTS

A total of 5,400 *Ae. aegypti* females per arm were released within the experimental houses during the trial. Almost all released mosquitoes in bedrooms treated with TIRS/CAIs were killed during the first 24 hours post-application for 2 weeks post-application (ranging from 94.3% to 97.3%; Figure 1B, Table 1). At 3 weeks post-application, the mortality had fallen but remained significantly higher than 80% (89.2; 95% CI: 79.98–98.35,  $t = 2.6$ , degrees of freedom [df] = 5). By the fourth week, the average mortality was statistically lower than 80% (85.3; 95% CI: 75.59–95.08,  $t = 1.4$ , df = 5), and from the fifth week onward, the desired efficacy of 80% was not reached and continued to decrease until week 8, the lowest level recorded (< 50%).

## DISCUSSION

Previously, we reported that IRS targeting mosquito resting sites with an appropriate insecticide can impact *Ae. aegypti* infestation rates and dengue transmission.<sup>22</sup> Although it is now a WHO-recommended procedure for control of *Aedes* spp.,<sup>5</sup> with numerous time-saving and cost advantages, TIRS still requires considerable investment to implement and sustain,<sup>5,17,20</sup> and is not always accepted by at-risk communities.<sup>22</sup> Here, we show that inhabitants of those communities could use over-the-counter insecticide aerosols to deliver TIRS within their own homes, with a single treatment providing 80–95% efficacy for 3 or more weeks thereafter. Moreover, with a carbamate-based insecticide mixture effective against the target population,<sup>24</sup> this is possible even where the vectors are resistant to pyrethroids.

Our data suggest that householder- or occupant-delivered TIRS could work as a complement to professional TIRS in situations where widespread insecticide coverage and relatively low residual efficacy (~ 1 month) are acceptable, for example, during dengue, chikungunya, or Zika outbreaks. With some guidance, communities can be instructed in the application of CAIs with residual power, particularly if including would be required, particularly with non-pyrethroid active ingredients, such delivery methods could be mobilized to far more rapidly than TIRS and provide an alternative to interventions that require the entry of ministry of health personnel into households.

The use of CAIs for the control of *Ae. aegypti* may induce insecticide tolerance in the mosquito populations and select insecticide resistance, mainly for pyrethroids,<sup>13</sup> considering that the use of household aerosol insecticides for mosquito control is highly prevalent in the Merida.<sup>13,14,25</sup> It is important to consider that the 100% of CAIs available in the local market of Yucatan contain at least one pyrethroid as active ingredient.<sup>26</sup> The selection of non-pyrethroid-based formulations is a good option to complement current control strategies, resistance management, and to overtake the negative impact of pyrethroid resistance on the efficacy of

pyrethroid-based CAIs.<sup>13</sup> Measuring the resistance of local *Ae. aegypti* populations must be taken into consideration and providing baseline data for program planning and pesticide selection before the start of control strategies. At least for Merida, the complete susceptibility to carbamates in the pyrethroid-resistant local populations is well documented.<sup>20,27,28</sup>

Whereas further research is merited, recent events have increased the value of self-administered vector control. The 2016 Zika pandemic highlighted the urgent need for simple affordable effective measures, in addition to the use of topical skin or clothing repellents, that those in exposed populations can adopt to protect themselves against *Ae. aegypti*. That situation is worse in 2020 as many countries in Latin America simultaneously face outbreaks of dengue<sup>29</sup> and the COVID-19 pandemic. As the restrictions on human movement imposed to reduce the spread of the COVID-19 are likely to seriously impede dengue vector control, the impact of the dengue outbreak is likely to be higher. Here is an exemplary situation where householder-led TIRS could empower those under threat from dengue, to not only protect their families from vector mosquitoes but also to do so without the additional risk of contracting COVID-19 infection from dengue control staff.

Nearly 94% of households reported using commercial insecticides on a regular basis (Gray et al.<sup>13</sup>), from which CAIs were the most common (70–90%),<sup>14,15</sup> with an estimated annual average expense per house of approximately \$570.00 Mexican pesos<sup>14,15</sup> indicating an annual market in excess of \$75 million Mexican pesos (> \$5.7 million USD) for Merida alone, the state capital.<sup>25</sup> Regrettably, most householders of Yucatan have, as preferred practice, to spray insecticide in the air and with formulations containing pyrethroids, which are the most common products available in the retail market.<sup>13,24</sup> This is a misuse (not so obvious for people) because air spraying of CAIs is poorly effective and does not confer sustainable protection, and it is even less effective when levels of insecticide of resistance to pyrethroids are elevated in local *Ae. aegypti* populations.<sup>27,30</sup>

Some householders from Yucatan spray CAIs over specific household surfaces to kill mosquitoes (still formulations containing the pyrethroids cypermethrin, cyfluthrin, and imiprothrin), although such formulations are marketed for ants, scorpions, and cockroaches (Gray et al.<sup>13</sup>, Dzib-Florez et al.<sup>24</sup>). A recent study with WHO cones evaluated locally commercially available residual surface sprays and found that the product here evaluated provided residual efficacy  $\geq 80\%$  of mortalities for up to 2 months on local pyrethroid-resistant *Ae. aegypti* populations when applied in different substrates typically present in urban residential premises (Dzib-Florez et al.<sup>24</sup>). Results of this study demonstrate that the immediate impact of TIRS can be delivered by one person using existing products, at an estimated cost for the average household in Mexico of under US\$3 per month. This has the potential to provide a lasting residual effect indoors compatible with the need for rapid and lasting mosquito control during arbovirus outbreaks and may be suitable for community-based TIRS. Triggered by early outbreak signs, dissemination via community hubs and mass/social media of instructions to treat the home immediately, with monthly re-treatment thereafter, provides a simple means to engage and empower householders. Compatible with integrated vector management strategies, it enables self-protection even if existing agencies

falter, a situation exemplified by the potential impact on vector control of the restrictions imposed during the 2020 COVID-19 pandemic.
